Single tensile overloads were applied to 4340 steel specimens which were treated to give 120 and 220 ksi yield strength levels. The influence of yield strength level on the number of nonsteady state crack growth cycles subsequent to the application of a 100 percent overload was noted to be substantial. The number of nonsteady state cycles for the 120 ksi yield strength steel was approximately an order of magnitude greater than that of the higher strength steel. A retardation model was developed using a residual stress intensity factor concept similar to that proposed by Willenborg et al. The model was found to predict to within 10 percent the number of nonsteady state crack growth cycles required to move a crack from the pre-overload position to a subsequent position, one overload induced plane stress plastic zone radius ahead of the pre-overload position. The model indicates that the reason for substantial increases in nonsteady state crack growth cycles observed for the low strength steel is due to a corresponding increase in the overload affected zone size.

FOREWORD

This report is the result of an in-house effort under Project 1467, "Analysis Methods for Military Flight Vehicle Structures," Work Unit 13470413, "Experimental Studies in Fatigue Crack Propagation in USAF Aerospace Structures." The work was conducted in the Air Force Flight Dynamics Laboratory at Wright-Patterson Air Force Base, Ohio by Dr. J. P. Gallagher, and Mr. T. F. Hughes (FBR). The effort covered the time period of February 1973 through February 1974.

Mr. Robert Mayle was responsible for the collection of the 120 ksi yield strength steel crack growth measurements and Mr. James Weirer collected the crack growth data for the 220 ksi yield strength steel. Mr. F. Hussong is acknowledged for his contributions in developing the crack measurement system utilized in this investigation. Mr. I. D. Hearne and Mr. H. D. Stalnaker were principally responsible for developing the test system. All tests were conducted in the Experimental Branch Test Facility (Bldg.65) which is under the direction of Mr. R. Cavanaugh.

This report was submitted by the authors February 1974.

This Technical Report has been reviewed and is approved.

FRANCIS J. JANIK JR.

Structures Division

ABSTRACT

Single tensile overloads were applied to 4340 steel specimens which were heat treated to give 120 and 220 ksi yield strength levels. The influence of yield strength level on the number of nonsteady state crack growth cycles subsequent to the application of a 100 percent overload was noted to be substantial. The number of nonsteady state cycles for the 120 ksi yield strength steel was approximately an order of magnitude greater than that of the higher strength steel. A retardation model was developed using a residual stress intensity factor concept similar to that proposed by Willenborg et. al. The model was found to predict to within 10 percent the number of nonsteady state crack growth cycles required to move a crack from the pre-overload position to a subsequent position, one overload induced plane stress plastic zone radius ahead of the pre-overload position. The model indicates that the reason for substantial increases in nonsteady state crack growth cycles observed for the low strength steel is due to a corresponding increase in the overload affected zone size.

SECTION I

INTRODUCTION

Variable amplitude load spectra when applied to cracked structures result in observations of crack movement which are at variance with simple no-load-interaction crack growth prediction techniques. One recognized facet of the crack growth behavior generated under spectrum loading is that substantially slower crack growth rates are observed when small amplitude load cycles are preceded by a load level with a higher maximum.

Several crack growth retardation models have been developed to predict this high-low load interaction effect. Wheeler (Reference 1) provided a model which identified the concept of a load interaction zone. He derived this model assuming that the ratio of interaction zones is directly related to the observed decrease in crack growth rates. Willenborg et al (Reference 2) used the Wheeler formulation of load interaction zones to derive a model which was based on the difference between load interaction zone sizes. Both of the above mentioned models were reformulated by Gallagher (Reference 3) to help identify the physical implications as well as to provide identifiable modeling forms for others who are directing their attention to a residual stress intensity factor concept.

The use of a residual stress intensity factor concept suggests that the local or effective stress intensity factor which is sensed by the propagating crack be calculated from

$$K^{eff} = K^{\alpha} - K_{R}$$
 (1)

where $K^{'''}$ is the stress intensity factor associated with remotely applied loads. The residual stress intensity factor (K_{R}) would in general be considered a function of many interacting variables, e.g.:

$$K_{R} = f \left(K_{max}^{OL}, K_{min}^{OL}, N_{OL}, K_{max}^{\infty}, R^{\infty}, \sigma_{ys}, N^{\infty}, \ldots\right)$$
 (2)

where $K_{\text{max}}^{\text{OL}}$ = maximum K_{max}^{∞} generated by the overload

 K_{min}^{OL} = minimum K_{min}^{∞} generated by the overload

 N_{OL} = number of overloads applied

 K_{max}^{∞} = maximum K^{∞} generated by the loads following the overload

 R^{∞} = stress ratio of remotely applied loads

 N^{∞} = number of cycles of K_{max}^{∞}

oys = yield strength level

SECTION II

TEST METHODS AND MATERIALS

MATERIALS AND SPECIMEN GEOMETRY

The nominal chemical composition of the one-half inch thick 4340 steel specimens which were employed in this investigation is given in Table I and the heat treatment schedules used to produce the 220 ksi and 120 ksi yield strength levels are given in Table II.

The geometry of the specimens is shown in Figure 1 and the corresponding stress intensity factor coefficient is given in Figure 2 from Reference 4.

2. TEST TECHNIQUES

A constant stress intensity factor condition was held throughout the tests such that an overload stress intensity factor $K_{\text{max}}^{\text{OL}}$ of 40 ksi $\sqrt{\text{in}}$ was followed by repeated cyclic load applications corresponding to a remotely calculated stress intensity factor varying between 2 and 20 ksi $\sqrt{\text{in}}$. The condition: $K_{\text{max}}^{\text{OL}} = 40$ ksi $\sqrt{\text{in}}$, $K_{\text{max}}^{\alpha} = 20$ ksi $\sqrt{\text{in}}$, $K_{\text{min}}^{\alpha} = 2$ ksi $\sqrt{\text{in}}$ was applied repeatedly to specimens heat treated to the two yield strength levels while observations of crack length movement were made. Prior to a reapplication of an overload, it was determined that the cracking rates associated with the $K_{\text{max}}^{\alpha} = 20$ ksi $\sqrt{\text{in}}$ condition were steady state and no longer appeared to be influenced by the previously applied overload.

A schedule of loads for any 0.025 inch increment on the crack path, as required by Figure 2 to achieve the desired constant stress intensity conditions, was developed prior to test start up and then utilized during the test. It was normally assible to define the surface crack position to within a 0.0005 inch tolerance since crack length measurements were made using a 20X Gaertner microscope mounted on a 1.0 inch Aerotech translation stage which was remotely controlled to move in 0.0001 inch increments.

- 2. Anneal at 1550°F for 1 hour in air
- 3. Slow cool specimen in sand from 1550°F to ambient temperature

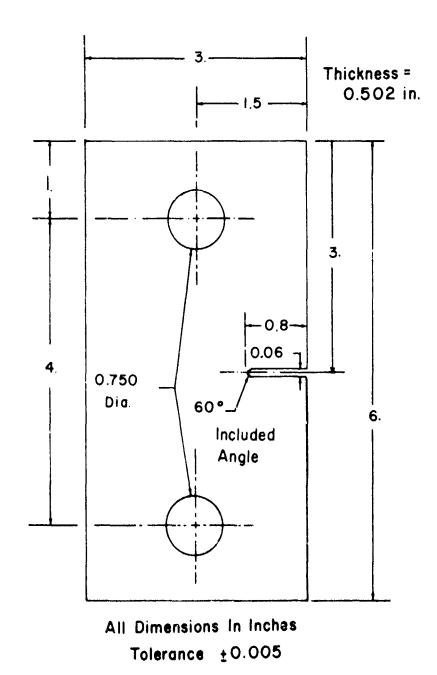

Figure 1. Geometry of Single Edge Notch (SEN) Specimen

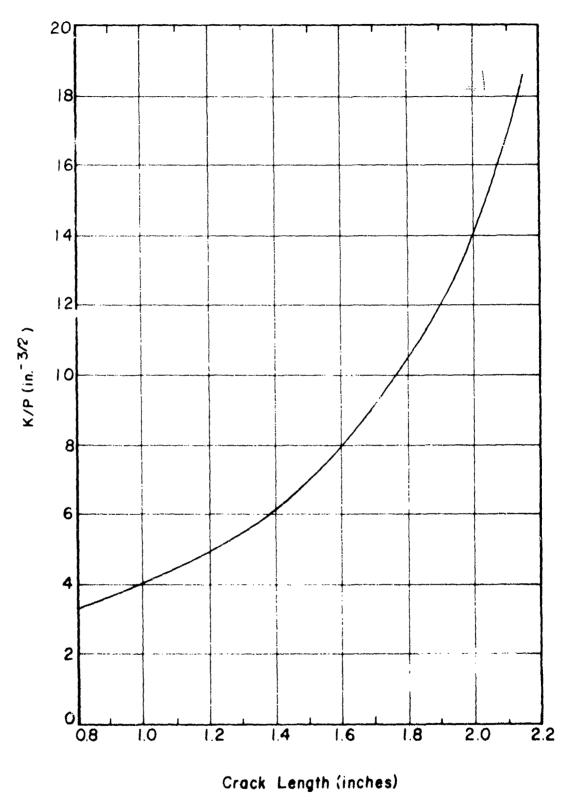

Figure 2. Stress Intensity Factor Calibration for SEN Geometry

Loads were applied to the specimen with a mechanical test system (hydraulically actuated, servo-controlled) which had a load cell mounted in series with the specimen. The frequency of applied loading was 10 Hz for the constant amplitude (sinusoidal wave) $K_{\text{max}}^{\infty} = 20 \text{ ksi } \sqrt{\text{in}}$, $K_{\text{min}}^{\infty} = 2 \text{ ksi } \sqrt{\text{in}}$ cyclic condition and approximately 0.05 Hz (manually applied) for the overload applications. The high frequency loading and a desiccated air environment were employed to limit the influence of any moisture induced environmental action (Reference 4).

SECTION III

RESULTS AND DISCUSSION

1. CRACK GROWTH BEHAVIOR

Detailed in Figure 3 is a schematic showing the parameters that have been utilized recently (References 5, 6, and 7) to characterize the overload affected crack propagation behavior. The nonsteady state (overload affected) region is defined in terms of cycles (N*) and distance (a*), termed the overload affected crack length, over which the reducing effect is observed.

The observed crack growth behavior of a crack which has been subjected to a single 100 percent overload (κ_{max}^{OL} = 40 ksi \sqrt{in} , κ_{max}^{∞} = 20 ksi \sqrt{in}) is presented in Figures 4 and 5 for the 120 and 220 ksi yield strength levels, respectively. The data are presented in terms of an incremental movement of the crack as measured from its position immediately prior to the overload application. The data shown in Figures 4 and 5 were utilized to find N* and a* for each overload application. Table III contains a listing of the observed N* and a* parameters and the steady state crack growth rates measured outside the delay region.

The average a* and N* parameters calculated using the data listed in Table III directly indicate the influence of yield strength on overload delay behavior. For the 120 ksi yield strength steel, the average overload affected crack length is 16.6 mils which is traversed in approximately 33,000 cycles; the corresponding values for the 220 km yield strength steel are 4.6 mils and 4100 cycles. On the mais of this information, one would have to rank the 120 ksi yield strength steel superior to the 220 ksi yield strength steel for spectrum load usage due to the significant increase in the number of reduced growth rate cycles observed in this steel. Furthermore, the average steady state crack growth rates for the 120 ksi yield strength steel are approximately a factor of 2.5 lower than those associated with the 220 ksi yield strength level.

OVERLOAD DELAY AFFECTED CRACK LENGTH

As discussed by Gallagher (Reference 3), both Wheeler (Reference 1) and Willenborg et al (Reference 2) assumed that the overload affected crack length would be a fraction of the overload established load interaction zone (z_{0L}) . Wheeler assumed that z_{0L} could be approximated by the overload created plane strain plastic zone radius while Willenborg et al utilized the overload plane stress plastic zone radius to characterize z_{0L} . The corresponding estimates of the overload affected crack length used by Wheeler and Willenborg et al are

$$a^{\star} \stackrel{\leq}{=} r_{0L}^{\star} = r_{y_{0L}}^{\star} = \frac{1}{4\sqrt{2}\pi} \left(\frac{\kappa^{0L}}{max}\right)^{2}$$
 (3)

and

$$a^* \leq z_{0L} \stackrel{\circ}{=} r_{y_{0L}} = \frac{1}{2\pi} \left(\frac{r_{max}^{0L}}{r_{ys}} \right)^2$$
 (4)

respectively,

Recently, several investigators (References 5, 6, and 7) have employed variations of the following relationship (r_0 is the plastic zone diameter for the applied overload) to show good correlation with measured overload affected crack lengths

$$a^* = r_0 = \frac{1}{2X + 6(1 - X)} \left(\frac{2}{\pi}\right) \left(\frac{K^+}{\sigma_{ys}}\right)^2$$
 (5)

where Probst and Hillberry (Reference 7) assumed $K^{+} = K_{MAX}^{OL}$ and both Von Euw et al (Reference 5) and Trebules e⁺ al (Reference 6) assumed $K^{+} = K_{max}^{OL} - K_{min}^{OL}$, and X represents the fraction of the cross section exhibiting shear lips. From the fracture surfaces, X was determined to be near zero for both yield strength levels for this investigation: Equation 5 reduces to

at $\stackrel{\sim}{=} r_0 = \frac{1}{3\pi} \left(\frac{k^+}{\sigma_{ys}} \right)^2$ (6)

for the case when X is zero

Table IV provides a direct comparison between the average overload affected crack lengths (a*) determined from the data given in Table III and the parameters calculated by Equation 3, 4, and 6 with $K^+ = K_{max}^{OL}$. It appears on the basis of this comparison that the Willenborg et all plane stress assumption provides the more viable approximation to the affected crack length.

TABLE IV

COMPARISON OF MEASURED AND CALCULATED AFFECTED ZONES

್ರ (KSI)	a* avg (in.)	r 0 (in.)	r* y _{OL} (in.)	r _{yOL} (in.)
120	0.0166	0.0118	.00625	0.0177
220	0.00456	0.00350	.00186	0.00525

Note that the inverse ratio of the two corresponding yield strength levels squared $\left(220/120\right)^2$ closely predicts the ratio of the average measured affected crack lengths (16.6/4.6). It is expected that future observations will further substantiate this influence of yield strength (in a given material) on the size of the affected crack length.

3. WILLENBORG ET AL MODEL PREDICTED CYCLES

One test for any crack growth predictive model is its ability to predict the number of cycles of applied load to achieve a given crack length change. The Willenborg et al model as detailed by Gallagher (Reference 3) takes a form identical to that given by Equation 1 where the residual stress intensity factor $K_{\rm p}$ is defined by

$$K_{R}^{W} = K_{max}^{OL} \left(1 - \frac{\Delta a}{z_{OL}}\right)^{1/2} - K_{max}^{\infty}$$
 (7)

where Δa is the crack growth into the overload load interaction zone (z_{OL}) . Following an overload, Δa is approximately zero and the reducing stress intensity factor is maximum. For the test conditions considered in this investigation, Equation 7 gives an initial K_R^W of 20 ksi \sqrt{in} . Equation 1 therefore predicts that the maximum effective stress intensity factor is zero at the crack tip.

The maximum effective stress intensity factor must be greater than the threshold (maximum) stress intensity factor (approximately 6 ksi \sqrt{in} for steels when R = 0) in order that fatigue crack growth occurs. The assumption expressed by Equation 7 must be in error since Table III shows that a finite number of cycles was required to propagate the crack through the overload affected crack length. Others (References 5 through 11) have also observed that cracks grow after single overload applications where $K_{\text{max}}^{\text{OL}}/K_{\text{max}}^{\infty} \stackrel{>}{=} 2.0$, the condition for which the Willenborg et al model predicts zero crack tip (effective) stress intensity factors.

4. ALTERNATE CRACK GROWTH DELAY MODEL

A more general approach to developing the residual stress intensity factor would suggest that $K_{\rm R}$ may be proportional to the Willenborg et al residual stress intensity factor expressed by Equation 7.

$$K_{\mathbf{R}} = \phi K_{\mathbf{R}}^{\mathbf{W}} \tag{8}$$

Consider the appropriate test conditions required to evaluate the proportionality factor ϕ . One boundary condition might be the "shut-off" overload to maximum load ratio $(K_{max}^{\rm OL}/K_{max}^{\infty})$ that produces no crack growth. This would be established using techniques similar to those employed by Probst and Hillberry (Reference 7). Assume that the shut-off overload level develops a local stress intensity factor condition such that no growth is induced. Since the fatigue threshold stress intensity factor maximum (K_{max}) is approximately constant for negative stress ratios (Reference 12), set the maximum local stress intensity factor $(K_{max}^{\rm eff})$

equal to K for zero tension loading (R = 0). Using Equations 7 and 8, K can be expressed as

$$\kappa_{\text{max}}^{\text{eff}} = \kappa_{\text{max}}^{\infty} - \psi \left(\kappa_{\text{max}}^{\text{OL}} \left(1 - \frac{\Delta a}{z_{\text{OL}}} \right)^{1/2} - \kappa_{\text{max}}^{\infty} \right)$$
 (9)

Immediately following the shut-off overload K_{max}^{OL} which produces no growth, Ca = 0 and $C_{max}^{eff} = K_{max}^{eff}$ and Equation 9 can be solved for ϕ subjected to these assumptions:

Probst and Hillberry (Reference 7) presented results in which increasing higher overloads eventually produced a condition of no crack growth for five different K_{max}^{ω} levels in 2024-T3 Aluminum. They found that the shut-off overload ratio was given by

$$K_{\text{max}}^{\text{OL}}/K_{\text{max}}^{\alpha} = 2.3$$
 (11)

for each K_{max}^{α} level studied.

5. CRACK GROWTH PREDICTIONS WITH NEW MODEL

In order to develop a estimate of the number of nonsteady state cycles (N*) associated with the overload affected zone the crack growth rates that result from each application of loading must be integrated over the overload affected zone. A Paris power law equation (Reference 13)

$$\frac{\Delta \mathbf{a}}{LN} = C\Delta \mathbf{K}^{\mathbf{p}} \tag{12}$$

was chosen as an adequate representation of the crack growth rate data for stress ratios less than 0.1 (assuming that tension only stress intensity factors establish $\pm K$).

The steady state crack growth equations used for predicting N* were

$$\frac{\Delta a}{\Delta N} = 1.376 \times 10^{-10} \ \text{LK}_{eff}^{3.2}$$
 (13)

for the 120 ksi yield strength steel and

$$\frac{\Delta a}{N} = 3.46 \times 10^{-10} \Delta K_{eff}^{3.2}$$
 (14)

for the 220 ksi yield strength steel. The exponent 3.2 was determined from independent tests on these two steels by others (References 4 and 14) and the pre-exponential constant was selected so that Equations 13 and 14 would intersect the average steady state crack growth rates at K = 18 ksi $\sqrt{\text{in}}$ given in Table III.

The effective stress intensity ranges used in Equations 13 and 14 were obtained either by subtracting K_{\min}^{eff} from K_{\max}^{eff} when K_{\min}^{eff} was greater than zero or by the value of K_{\max}^{eff} when K_{\min}^{eff} calculated using Equations 1 and 9 was less than zero.

The parameter ; defined by Equation 10 was estimated on the basis of two assumptions: (1) the shut-off overload ratio for the steels investigated is close to that defined by Equation 11 and (2) $K_{\text{max}_{\text{TH}}}$ for steels is approximately 6 ksi $\sqrt{\text{in}}$ for a stress ratio of zero. Equation 10 subjected to these two assumptions becomes

$$z = \frac{1 - 6/K_{\text{max}}}{1.3} \tag{15}$$

A numerical integration approach was employed to estimate the number of applied cycles required to propagate the crack from its preoverload position to a position one plane stress (overload) yield zone radius (Equation 4) ahead of the preoverload position. One-tenth of the plane stress yield zone radius was thought to be an adequate increment in the integration scheme. Table V lists the calculations corresponding to the development of the predictions based on the new model defined by Equations 1, 7, 8, 15, and 13 or 14. Table VI summarizes the results of a *, N*, ry, N** (average number of N measured to achieve ryOL and the corresponding predictions associated with both the Willenborg et al and new models. As can be discerned from Table VI, the new model predicts (to within 10 percent) the number of cycles observed to achieve ryOL. The new model is also noted to be conservative since steady state rates are predicted in a shorter number of cycles than was observed.

6. PREDICTION OF CRACK GROWTH RATES USING NEW MODEL

The crack growth data presented in Figure 4 were used to obtain the cyclic crack growth rates for the 120 ksi yield strength 4340 steel listed in Table VII. The fatigue crack growth rate data for the first five singularly applied overloads are presented graphically in Figure 6. While the magnitudes of the crack growth rates associated with each curve plotted are noted to be similar, there appears a tendency for the shape of the trough in the curve to become flatter and longer with each succeeding overload. This observation is reinforced when Table VII is used to compare the growth data for the first and second overload to that for the seventh and eighth overload. The reason for this change in crack

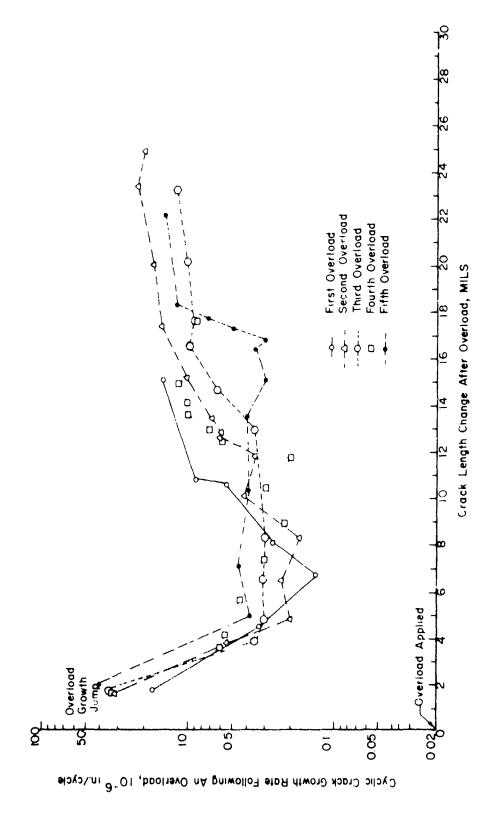

Figure 6. Crack Growth Rate Behavior Following an Overload $\left[\binom{K0L}{max}/K_{max}\right]=2.]$ (First five Overloads) for 120 $\,$ i Yield Strength 4340 Steel

growth behavior with each successive overload is due to the thru-thethickness crack front curvature changes which will be discussed below.

Table VIII provides a summary of the crack growth rate behavior for the first five singularly applied overloads as a function of the crack movement subsequent to the applied overload. These data were then used to obtain the average growth rates as a function of position for the first four and first five overloads. Table V lists the crack growth rates computed using the model as a function of incremental position in the overload affected zone. Figure 7 presents the average growth rate for the first four and first five overloads (see Table VIII) and the calculated crack growth rates for the new model.

Figure 7 shows that the observed behavior is substantially different from the model prediction in that the observed growth rates reduce gradually to their lowest level while the model predicts an abrupt change in growth behavior followed by a monotonically increasing growth rate. It can be noted that the model's monotonically increasing crack growth rate parallels the observed average growth rate behavior as it again increases to its steady state level. If the steady-state crack growth region at the end of the $r_{y_{OL}}$ (i.e. 4.7 mils) is shifted to a position

prior to the beginning of the growth delay region, the model behavior closely describes the average growth rate curves (see Figure 8).

7. BELOW THE SURFACE

It was assumed that the crack growth behavior observed on the surface was identical to that which was occurring within the specimen. Failure of the specimen revealed that following the initial overload, the surface crack movement in the 120 ksi yield strength steel specimen lagged the crack movement in the center of specimen by an increasing amount with each additional overload application. Detailed in Table IX is a listing of the surface and internal crack movements as related to applied overload and constant amplitude cycles between overloads. The prior to overload application crack position on the surface and at the center of the secimen is tabulated in Table X.

^{*} OVERLOAD 1A HAD A REDUCED KOL Kmax of 1.8

Note is made in Table IX of the incremental jump in the center of specimen crack position that occurs during the overload cycle. This jump phenomenon has also been observed by Von Euw et al. (Reference 4) and by Hall (Reference 15). The average crack jump during the overload was approximately 2.5 mils, approximately two orders of magnitude higher than what would have been calculated using a steady state growth rate at a $\pm K = 40$ ksi \sqrt{in} . The present model does not account for accelerated growth.

It is suspected that a generalization of the use of the load interaction zone concept (Reference 3) could be employed as a first step in modeling the jump phenomenon. For example, consider Figure 9 where the base line no retardation curve (K^*) has been established for a low level loading which produces steady state growth. A high level load is applied at crack length $a_{\rm OL}$, establishing a subsequent no retardation curve (K^*). Assume that the incremental movement (accelerated growth) accompanying the application of the high load is related to the difference between the two no retardation curves (i.e., K^* and K^{**}). Taking the same approach that was employed in the development of the retardation model presented above, one could set the residual stress intensity factor equal to a proportionality factor multiplied by the difference in the no retardation stress intensity factors, i.e.

$$K_{R} = -A (K^{**} - K^{*})$$
 (16)

which would then be used in conjunction with Equation 1 to calculate the rate of crack advance. Insufficient evidence precludes any further discussion of the applicability of the load interaction concept as applied to overload induced crack growth acceleration.

Since the crack growth behavior obtained through surface observations is significantly different from that noted along the center of the failed specimen, it is difficult to place full confidence in the crack growth rate behavior generated using surface growth data. Possibly, there is a rather abrupt deceleration in crack advancement following an overload but this question will have to be addressed by future investigations of the delay phenomenon.

Using the internal crack tip position (see Table X) and the known applied loads employed to control stress intensity factor variables on the basis of surface measurements, it was possible to determine the change in the stress intensity factor variables associated with the midspecimen position. The average constant amplitude stress intensity range was 19 ksi $\sqrt{\text{in}}$. It changed from 18 to 20 ksi $\sqrt{\text{in}}$ between the first overload and the last constant amplitude cycle. The average K_{max}^{∞} was 21 ksi $\sqrt{\text{in}}$, while the average $K_{\text{max}}^{\text{OL}}$ was 42 ksi $\sqrt{\text{in}}$. Table XI provides the calculations for the retardation model behavior with the mid-stress intensity factor specimen conditions. Following the numerical integration through the overload affected zone (a* = 14.6 mils) the crack was allowed to move to the average ℓ a int position (see Table IX). The calculated number of cycles is approximately 94 percent of the average number of constant amplitude cycles applied between overloads.

^{* 37.40} was taken as average movement between overloads (see Table IX) which could be associated with an average number of cycles (N_{avg}) of 42,600 to produce this growth: N_{M}/N_{AVG} = .941

SECTION IV

SUMMARY

Significant differences in delay cycles were observed when the yield strength of a 4340 steel was varied from 120 to 220 ksi. Subjecting specimens to controlled stress intensity factor conditions: single peak overloads with $K_{max}^{OL} = 40$ ksi \sqrt{in} followed by constant amplitude cycling with $K_{max}^{\infty} = 20$ ksi \sqrt{in} ($R^{\infty} = 0.1$), indicated that for the same external loading (e.g., spectrum loading) more retardation can be expected from a steel with lower yield strength.

Following the development of a retardation model based on overload shut-off and threshold stress intensity factor conditions, it was possible to show that a lower strength steel gives more retardation for a given loading condition primarily because its overload created load interaction zone is significantly larger.

The retardation model developed herein was found to predict to within 10 percent the cycles required to propagate a crack from its position immediately prior to overload application to a subsequent position a distance one plane stress plastic zone radius ahead of its pre-overload position. Crack growth rates obtained from surface measurements were not adequately predicted by the retardation model but note was made of similarities in predicted growth rates and observed behavior.
